Background: Age-related loss of the muscle mass is linked to obesity and diabetes because the muscle is the major site for fat oxidation which is influenced by exercise. We aimed to explore the association between fat oxidation rates (FORs) and exercise intensity during age-related muscle loss.

Methods: A total of 224 healthy Chinese men aged 23–92 years were recruited. Fat and lean tissue masses were measured by DXA. The subjects were also tested using graded incremental exercise with an increased intensity of 10 W until maximal fat oxidation rate (Fatmax) was achieved. Real-time contribution (%) of fat to total energy expenditure were determined using indirect calorimetry.

Results: We found that appendicular skeletal muscle mass/weight (ASM/Wt) decreased during ageing and positively correlated with FORs during low-intensity exercise. In multiple linear regression models, FORs was positively related with ASM/Wt (β =0.446, P=0.0091) but negatively associated with exercise intensity (β =−0.573, P<0.0001), whereas fat oxidation rate did not show any association with age. Moreover, there was a significantly negative correlation between ASM/Wt and Fatmax.

Conclusions: Our findings highlight the importance of muscle mass in fat utilization during low-intensity exercise. A higher exercise intensity indicated by Fatmax is recommended for improving fat oxidation in Chinese men with decreased muscle mass.

Introduction

Skeletal muscle comprises about 40% of total body mass in a healthy-weight individual (1). Ageing is associated with body composition changes, with increased visceral fat and reduced muscle mass (2). Sarcopenia is defined as the loss of muscle mass and strength due to the ageing, and is associated with insulin resistance and metabolic syndrome. The changes in skeletal muscle are especially important because muscle is the major site for substrate utilization (3). Previous studies have indicated that skeletal muscle and the heart consume around 30% of resting energy consumption and almost 100% of increased energy during exercise (4). Moreover, carbohydrate (CHO) and fat provide the vast majority of fuel required by skeletal muscle (5).

The ageing muscle is characterized by fat infiltration (6). Thus, the accumulation of lipids within the muscles is an important factor leading to insulin resistance (7).
A research on obesity men showed that the exercise eliciting the maximal fat oxidation but not high-intensity interval training reduced insulin resistance significantly (8). In addition, previous studies have reported that fat oxidation rates (FORs) which predominantly contribute to energy expenditure is influenced by several factors, such as muscle mass, activity state, exercise intensity, exercise mode and nutrition (9,10).

Exercise has been explored as one of the most important factor influencing fat utilization. In general, the fractional contribution of CHO to the fuel supply is small at low intensity and rises with the exercise intensity increase (11), whereas FORs reaches its peak at moderate exercise intensities normally ranging between 55% and 65% of maximal oxygen uptake (12). The exercise intensity, at which ‘maximal fat oxidation rate’ (Fatmax) occurs, has been defined as Fatmax intensity. Thus, the Fatmax intensity would maximize the beneficial effects of exercise. According to the published data, muscle fatty acid oxidative capacity is a determinant of whole body fat oxidation during physical activities (13). However, the implied relationship between FORs and exercise intensity during ageing has still not been clearly investigated.

Therefore, we chose healthy men of various ages who did not suffer from metabolism disorders to assess fat oxidation, as determined using a cycle-ergometer during graded incremental exercise, and muscle mass tested by DXA. The purpose of this study was to identify the association between FORs and exercise intensity in the context of age-related muscle loss. The results of this study will contribute to the development of an effective exercise regimen for elderly men to achieve Fatmax. We present the following article in accordance with the STROBE reporting checklist (available at http://dx.doi.org/10.21037/apm-20-611).

**Methods**

**Subjects**

The clinical study was approved by the Ethics Committee of the First Affiliated Hospital of Nanjing Medical University, Jiangsu, China (No.2019-SR-481), in accordance with the Declaration of Helsinki (as revised in 2013). Written informed consents were obtained from all participants. Subjects were excluded if they were weight unstable (gained >2.0 kg in the previous 6 months), or had chronic disease (e.g., renal, hepatic, pulmonic, cardiovascular disease or cancer). Ultimately, 224 healthy Chinese men, aged 23–92 years, were recruited for this study. 121 were given a graded incremental exercise test. The remaining were either lost on follow-up, did not provide consent or were unable to tolerate the exercise intensity experiment. Fasting levels of glycated hemoglobin, cholesterol, triglycerides, low-density lipoprotein, and high-density lipoprotein were obtained.

**Biochemical analysis**

After overnight fasting, blood samples of participants were obtained and centrifuged at 4.0 °C for 10 min at 1,000 rpm and subsequently analyzed. Plasma glucose was determined using the YSI 2300 STAT Plus glucose oxidase assay (Yellow Springs Instruments, Yellow Springs, OH, USA). Serum insulin was measured using a radioimmunoassay (EMD Millipore, Billerica, MA, USA). Serum triglycerides (TG) and cholesterol were analyzed using enzymatic methods with an automated platform (Roche Modular Diagnostics, Indianapolis, IN, USA). Serum triiodothyronine (FT3), thyroxine (FT4), and thyroid stimulating hormone (TSH) levels were measured using the Abbott AxSYM Immunoassay system (Abbott Laboratories, Abbott Park, IL, USA) with intra- and inter-assay coefficients of variation of <10% for all measurements.

**Measurement of body composition**

Total and regional (trunk, android, gynoid, limbs) fat and lean tissue masses were measured using a Hologic Discovery A (Hologic Inc., Bedford, MA, USA) and analyzed by Encore Software 11. Trunk fat and lean masses were designated from the pelvis cut (lower boundary) to the neck cut (upper boundary). Appendicular skeletal muscle mass (ASM) was calculated as the sum of the muscle masses of the arms and legs.

**Measuring rest energy expenditure (REE) by indirect calorimetry (IC)**

The participants visited the metabolic laboratory between 07:00 am and 11:00 am after a 12 h fast and abstaining from any form of physical activity (other than walking) prior to completing a ventilated, open-circuit IC measurement (Quark PFT Ergo, COSMED SRL, Rome, Italy). The principle of IC is derived from the fact that the human body burns available sources of fuel using oxygen while producing CO2. Only stable measurements for at least 20 minutes were considered acceptable. Oxygen consumption and CO2 production were measured and the respiratory quotient (RQ)
and REE calculated using the VCO2-based Weir equation (REE = 5.534 × VCO2 × 1440) (14). To ensure quality control between participants and technicians, gas analyzers were calibrated to <0.1% standard gas and flow rate and volume were calibrated to ≤3% error.

**Graded exercise protocol and energy expenditure**

The experimental trial was performed in the morning after a minimum 10-h overnight fast. All subjects were asked to refrain from exercise, alcohol, smoking, and caffeine for the 24 h period preceding the test. After a 15-min seated resting period, the subjects were seated on the cycle-ergometer and given a graded incremental test. After a standardized 5.0-min warmup at a 0.0-Watts (W), the intensity was increased by 10 W (10 W-20 W-30 W-40 W-50 W-...) every 5 min until the exercise heart rates of the subjects achieved 70% of the age-predicted maximum (220-age), which was defined as hard-intensity exercise. The real-time energy consumption, respective contribution (%) of fat to total energy expenditure were determined using indirect calorimetry (Quark PFT Ergo, COSMED SRL, Rome, Italy). Fat\_max intensity is the exercise intensity that causes the highest rate of fat oxidation, which is usually considered to occur at 45–60% of peak maximal oxygen uptake, defined as moderate intensity with 50–69% of maximal heart rate; therefore, after incremental exercise, Fat\_max can be determined using the real-time fat oxidation reporting system of indirect calorimetry.

**Statistical analysis**

Descriptive data for the subject characteristics were presented as mean ± standard deviation (SD). The association between fat oxidation rates, Fat\_max and age, appendicular skeletal muscle mass/Weight (ASM/Wt), total fat mass were determined using Pearson correlation analysis. Multiple linear regression models were further applied for fat oxidation rates analyses, using Age, Exercise intensity and ASM/Wt data. All statistical analyses were performed using IBM SPSS Statistics for Windows (Version 20, IBM Corp, Armonk, NY, USA) and P<0.05 was considered statistically significant.

**Results**

**Skeletal muscle mass decreased during ageing**

A total of 224 healthy Chinese men were included in the analysis, with data obtained from the baseline visit of a clinical trial. Skeletal muscle is a metabolically active tissue that is critical to maintaining whole-body homeostasis. Recent study reported that ASM/Wt was related with insulin resistance (15), and ASM/Wt was the more appropriate index for sarcopenia (16). Pearson correlation analysis showed that ASM/Wt was negatively correlated with the age (r =−0.260, P<0.0001) (Table 1, Figure S1). In addition, as shown in Table 1, ASM/Wt was negatively associated with WHR (r =−0.206, P=0.004) and total fat mass (r =−0.409, P<0.0001). ASM/Wt showed a positive relationship with TG (r =0.137, P=0.04) and negative relationship with fasting insulin (r =−0.228, P=0.018). However, there was no statistical association between ASM/Wt and fasting glucose, HDL-C, HAc1%, 25(OH)VD and thyroid function including FT3, FT4 and TSH.

**Increased ASM/Wt improves fat oxidation rate during low-intensity exercise**

Age-related muscle loss is associated with metabolic syndrome and muscle is the major site for fat utilization. Thus, we performed correlation analysis between ASM/Wt and fat oxidation rate during an exercise intensity of 10–50 W. The results showed a significantly positive correlation between ASM/Wt and fat oxidation rates during low-intensity exercise (10 W: r =0.252, P=0.008 and 20 W: r =0.199, P=0.039; Figure 1A,B), while there was no correlation during moderate exercise (30–50 W: P>0.05, Figure 1C,D,E).

**No relation between ASM/Wt and fat oxidation rate in the resting state**

Resting energy expenditure (REE) is defined as the amount of calories required by the body at rest during a 24 h period and represents 70% to 80% of the calories used by the body. Pearson correlation analysis revealed no correlation between ASM/Wt and REE (Figure S2A, Supporting information). Moreover, there was no significant association between ASM/Wt and fat oxidation rate (Figure S2B).

**Analyses of Fat oxidation rate on Age, ASM/Wt and exercise intensity**

Considering that ageing is associated with impaired muscle mass and quality, we further performed correlation analysis between age and fat oxidation rate during an exercise intensity of 10–50 W. The results showed a significantly
A negative correlation between fat oxidation rate and age during low-intensity exercise (10 W: \( r=−0.178, P=0.077 \) \( \text{Figure 2A} \); 20 W: \( r=−0.202, P=0.045 \) \( \text{Figure 2B} \)), but not during moderate exercise (30–50 W \( \text{Figure 2C,D,E} \)).

Given the significant relationship between age, ASM/Wt, exercise intensity and fat oxidation rate, we further performed multiple linear regression analysis (\( \text{Table 2} \)). Fat oxidation rate was positively correlated with ASM/Wt (\( \beta =0.446, P=0.0091 \)) but inversely associated with Exercise intensity (\( \beta =0.573, P<0.0001 \)), while fat oxidation rate did not show any association with age. Taken together, these results highlight the significance of muscle mass of Chinese men in fat utilization during light-intensity exercise.

### The Chinese men with decreased muscle mass need a higher exercise intensity for Fat\(_{\text{max}}\)

The subjects were tested using a graded exercise protocol with the intensity being steadily ramped from no load (0.0 W) to an increase of 10 W every 5 min until reaching Fat\(_{\text{max}}\), and the correlation between Fat\(_{\text{max}}\) and body parameters was determined. The results showed significantly positive correlations of Fat\(_{\text{max}}\) with BMI and total fat (\( r =0.459, P<0.0001 \) and \( r =0.348, P=0.0002 \), respectively; \( \text{Figure 3A,B} \)), but a negative correlation between Fat\(_{\text{max}}\) and ASM/Wt (\( r =−0.244, P=0.011 \); \( \text{Figure 3C} \)).

### Discussion

Lean muscle mass accounts for about 50% of total body weight in young adults, but decreases to only 25% of total body weight in old people aged 75–80 years (17). Evidence from our data also indicated that ASM/Wt was negatively correlated with the age. Moreover, we found that legs lean masses decreased much more than arms lean masses during ageing, consistent with previous observations (18).

Skeletal muscle is a metabolically active tissue that is critical to maintaining whole-body homeostasis. It has

been well established that older people have a lower rest energy expenditure (REE) which is decreased by about 30% between the ages of 20 and 70 years (19,20). Some studies have shown that more muscle mass increases REE (21), but other studies have opposite finding, for example, a study did not demonstrate a low REE in Duchenne Muscular Dystrophy (DMD) males (22). Our present study showed that REE decreased during ageing, but we observed no correlation between ASM/Wt and REE. This might be due to other determinants of REE, such as fat mass, food intake and physical activity habit, which are not considered in this study. It is also possible that skeletal muscle mass plays more important role in the energy expenditure during exercise training than in the resting state.

Moreover, skeletal muscle is the major site for substrate utilization especially during exercise. Carbohydrate (CHO) and fat provide around 90% of the fuel for skeletal muscle during contraction activity (23). Several studies have shown that the oxidation of lipid contributes significantly to overall energy needs with most of the energy requirements of muscle being obtained via fatty acid oxidative (FAO) (24,25). Fat deposit of muscle has been thought as a strong risk factor of heart disease, type 2 diabetes, and the metabolic syndrome. Furthermore, regular physical activity prevents both the age-associated loss of muscle strength and increase in muscle fat infiltration in older adults (26). Although the mechanisms of muscle loss induced insulin resistance are complex, an inability to oxidize lipids appears to be an important factor (27). An increased capacity to oxidize fat during exercise in patients with T2DM can reduce their dependence on glucose as a source of energy. In addition, increased fat oxidation through physical activity improves insulin sensitivity (28). In our study, we found no statistical association between ASM/Wt and fat oxidation rate and CHO rate when people are in a state of rest. Nevertheless, we found a significantly positive correlation between ASM/Wt and fat oxidation rates during low-intensity exercise (10 W and 20 W), indicating that individuals with more muscle mass have an increased capacity to oxidize fat during low-intensity exercise.

In our study, we found that fat oxidation rates do not vary with age. However, we found a significant correlation of fat oxidation rate with muscle mass. This indicates that ageing itself does not affect fat oxidation, but loss of muscle mass during the ageing process does. It is thus important that elderly individuals maintain or increase muscle mass through lifestyle changes such as increased physical activity or better nutrition. Larger muscle mass will lead to higher fat oxidation rates, which will reduce comorbidities and improve quality of life.

Figure 3 Correlation between body components and maximal fat oxidation rate (Fat$_{max}$). (A,B,C) Regression line for body mass index (BMI), total fat mass, appendicular lean skeletal/weight (ASM/Wt) and age and Fat$_{max}$.
Fat\textsubscript{max} intensity is the exercise intensity that causes the highest rate of fat oxidation. Therefore, after incremental exercise, Fat\textsubscript{max} can be determined using the real-time fat oxidation reporting system of indirect calorimetry. Previous studies have demonstrated that Fat\textsubscript{max} intensity is variable among individuals (29,30). For example, A research reported that Fat\textsubscript{max} intensity was higher in obese individuals than in lean controls (31). The exercise intensity for Fat\textsubscript{max} was significantly lower in the T2DM group than the control group (32). Another novel finding of this study was that most of the subjects achieved the Fat\textsubscript{max} during a workload of 10–20 W and there was a strong positive correlation between body fat mass and Fat\textsubscript{max} intensity in contrast to a significant negative correlation between muscle mass and Fat\textsubscript{max} intensity. These findings suggest that Chinese men with decreased muscle mass might need more intense exercise to achieve Fat\textsubscript{max}.

As the muscle is important for blood glucose homeostasis and increase insulin sensitivity, diabetes and hyperlipidemia are more common in older than in younger individuals. Thus, we examined the relationship of ASM/Wt with multiple clinical variables of glucose and lipid metabolism. We demonstrated that fasting insulin decreased with higher ASM/Wt, suggesting insulin resistance in subjects with loss of skeletal muscle mass. Although strong evidence indicates that individuals with muscle loss have increased risk of insulin resistance, the relationship between muscle loss and lipid metabolism requires further elucidation. For example, several studies indicated a negative association between muscle loss and lipid metabolism biochemical markers (33,34). However, our data showed that the triglycerides level was significantly lower in people with muscle loss. One possible explanation is that not all adipose tissues are metabolically equivalent (35), thus the older people with lighter body weight and without abdominal obesity may contribute to the decline of triglycerides. Meanwhile, ASM/Wt was found to be positively related with FT3. There is increasing evidence that thyroid hormones play a role in muscle loss process (36), for example, in one study hyperthyroid mice exhibited higher muscle fatigue (37).

The large age range required for this study holds specific limitations. For example, there was large variability in parameters such as fasting insulin and cortisol levels between participants. Furthermore, older individuals have different activity levels and dietary habits to their younger counterparts. The study could have been improved if we had acquired data on activity levels and dietary habits, and standardized accordingly. Finally, our study population is small. With a larger population, direct comparisons within age brackets can be made, increasing the applicability of our findings.

In conclusion, our findings highlight the importance of muscle mass in fat utilization during low-intensity exercise. A higher exercise intensity indicated by Fat\textsubscript{max} is recommended for improving fat oxidation in Chinese men with decreased muscle mass. These results could be useful when considering an exercise regimen to improve health in elderly men.
