Background: The aim of this study was to investigate the pulmonary function of patients with 2019 novel coronavirus (COVID-19)-induced pneumonia.

Methods: A retrospective analysis of 137 patients with COVID-19-induced pneumonia who were discharged from the Enze Hospital, Taizhou Enze Medical Center (Group) from January 31 2020 to March 11 2020 was conducted. Follow-up occurred 2 weeks after hospital discharge, during which patients underwent a pulmonary function test.

Results: Of the 137 patients who underwent a pulmonary function test 2 weeks after discharge, 51.8% were male, and the mean age was 47 years. Only 19.7% of the patients were identified as having severe COVID-19-induced pneumonia. The pulmonary function tests showed that for a small number of patients the forced expiratory volume in one second/forced vital capacity ratio (FEV1/FVC) % values were <70%, and the mean forced inspiratory volume (IVC) and FVC values were 2.4±0.7 and 3.2±0.8 L, respectively. In severe cases, 88.9% of patients had an IVC <80% of the predicted value, and 55.6% of patients had an FVC <80% of the predicted value. The proportion of patients with maximum expiratory flow rate at 25%, 50% and 75% of the vital capacity (MEF25, MEF50, and MEF75) values <70% were 55.6%, 40.7%, and 25.9%, respectively. In the non-severe group, 79.1% of patients had an IVC <80% of the predicted value, and 16.4% of patients had an FVC <80% of the predicted value. The mean MEF25, MEF50, and MEF75 <70% values were 57.3%, 30%, and 13.6%, respectively.

Conclusions: Our results demonstrated that the pulmonary function of patients with COVID-19-induced pneumonia predominantly manifested as restrictive ventilation disorder and small airway obstruction, which was increased in critically ill patients.

Introduction

The 2019 novel coronavirus (COVID-19) is a viral infectious disease that is now a widespread concern (1-3). The most severe symptom of COVID-19 is severe acute respiratory distress syndrome, which can lead to rapid death (1). Significant injury to type II alveolar epithelial cells induces pulmonary fibrosis through cytokine storm and immunopathology (4). Pulmonary fibrotic changes are occasionally observed in response to viral infections, and can manifest as a consequence of several respiratory viral infections, such as Middle East respiratory syndrome (MERS) and avian influenza (5). In particular, in the 2003 epidemic of severe acute respiratory syndrome (SARS), it was observed that many patients who survived the severe illness developed residual pulmonary fibrosis, with increased severity seen in older patients (6). Varying degrees of fibrosis have also been observed in autopsies of fatal COVID-19 cases (7). In the later period of COVID-19-induced illness, the infection predominantly manifests as organized pneumonia and fibrosis in clinical findings and radiography (8). Despite these observations, the pulmonary function of patients with COVID-19-induced pneumonia has not yet been reported on. The purpose of this study was to investigate pulmonary function and treatment strategies for patients with COVID-19-induced pneumonia. We present the following article in accordance with the STROBE reporting checklist (available at http://dx.doi.org/10.21037/apm-20-1688).

Methods

Study design and patients

This was a retrospective, observational, single-center study. The study was registered in the Chinese Clinical Trial Registry (ChiCTR2000029866). The study was conducted in accordance with the Declaration of Helsinki (as revised in 2013). Ethics approval was granted by the Hospital Ethics Committee of Enze Hospital of Taizhou Enze Medical Center (Group). Patients with laboratory-confirmed COVID-19 who improved and were discharged were consecutively included. Written informed consent was obtained from all participants before inclusion.

The diagnostic criteria was based on laboratory (nucleic acid)-confirmed infection with COVID-19 and lung involvement confirmed by chest imaging. The discharge criteria included the following: (I) temperature returned to normal for at least 3 days; (II) significant improvements in respiratory symptoms; (III) an imaging study showed significant lung inflammatory uptake; (IV) two consecutive COVID-19-negative respiratory pathogen nucleic acid detection results (sampling time interval of at least 1 day). Patients were excluded if they were pregnant. The diagnostic criteria for severe patients were as follows: (I) respiratory distress [respiratory rate (RR) >30 breaths/ min at rest]; (II) mean oxygen saturation ≤93%; arterial oxygen pressure/oxygen concentration (PaO$_2$/FiO$_2$) ≤300 mmHg; (III) chest imaging lesion progression >50% within 24–48 hours (9).

Pulmonary function test

The pulmonary ventilation function test was performed in accordance with the operating instructions for the American Thoracic Association pulmonary function test via an automatic pulmonary function testing system (made in Germany) (10). Testing parameters included forced expiratory volume in the first second (FEV$_1$), forced inspiratory volume (IVC), forced expiratory volume in the first second as a percentage of the expected value (FEV$_1$/IVC), maximum expiratory volume at 75% of the vital capacity airflow rate (MEF75), maximum expiratory flow rate at 50% of the vital capacity (MEF50), and maximum expiratory flow rate at 25% of the vital capacity (MEF25). Each test was repeated 3 times, and the most standard waveform were used. FEV$_1$/FVC <70% was defined as obstructive ventilation dysfunction, FVC or IVC <80% of the predicted value indicated restrictive ventilation dysfunction, and a value of <70% of the predicted value defined impaired MEF 25–75% values.

Data collection

All patient data were extracted from electronic medical records and included age, sex, smoking history, chronic obstructive pulmonary disease history and pulmonary function measures. The last follow-up was completed on 25 March 2020. Chest computed tomography (CT) was used for the imaging analysis.

Statistical methods

Data are expressed as the mean±standard deviation (SD), median with interquartile range or percent with number of patients. Normality was evaluated by using the Shapiro-Wilk test (P value >0.05). Comparisons between groups
of continuous variables, which were normally distributed, were carried out using Student’s t-test or a corrected t-test. Comparisons of other scenarios were performed using the Mann-Whitney U test. Comparisons of categorical variables were performed using the \( \chi^2 \) test or Fisher’s exact test. P values <0.05 were considered significant. All statistical analyses were performed with SPSS 26.0.

Results

A total of 137 patients with COVID-19 underwent pulmonary function tests 2 weeks after hospital discharge. All patients were included in the analysis and no patients were lost to follow-up for 2 weeks. No patients used ventilator or extracorporeal membrane oxygenation (ECMO). The mean age was 47 years, and 51.8% were male. Among all patients, 6 patients (4.4%) had a smoking habit, and 2 (1.5%) patients had a history of chronic obstructive pulmonary disease (COPD) (Table 1). The IVC and FVC values were significantly reduced in severe cases compared to mild cases (P<0.05), and the mean IVC and FVC values were 2.4±0.7. The \( \text{FEV}_1 / \text{FVC} \) value was 82.7%±7.4% (Table 1).

Furthermore, 81.0% of patients had an IVC <80% of the predicted value, and 24.1% of patients had an FVC <80% of the predicted value. In severe cases, 88.9% of patients had an IVC <80% of the predicted value, and 55.6% of patients had an FVC <80% of the predicted value. The proportion of patients with MEF25, MEF50, and MEF75 <70% values were 55.6%, 40.7%, and 25.9%, respectively. In the non-severe group, 79.1% of patients had an IVC <80% of the predicted value, and 16.4% of patients had an FVC <80% of the predicted value. The mean MEF25, MEF50, and MEF75 <70% values were 57.3%, 30%, and 13.6%, respectively, indicating small airway dysfunction (Figure 1).

Discussion

Approximately 200 million people develop viral pneumonia worldwide each year (11). In the past 10 years, this has been exacerbated by the addition of SARS, avian influenza virus (H1N1 and H7N9) and MERS outbreaks (12-14). In patients with viral pneumonia, post-acute respiratory distress syndrome (ARDS) pulmonary fibrosis and
pulmonary dysfunction are observed complications and the cause of pulmonary fibrosis is lung tissue inflammation damage, tissue structure destruction, fibroblast proliferation and a large amount of extracellular matrix accumulation (14). In long-term follow-up of patients, the rates of post-ARDS fibrosis and pulmonary dysfunction in patients with influenza are 10% and 54.2%, respectively (14,15). In this study, we found reduced IVC and FVC values in 81.0% of patients. Impaired MEF25–75% values were indicative of small airway dysfunction (Figure 1). Our results showed that most patients displayed restrictive ventilatory dysfunction. Furthermore, the IVC decreases were greater than the FVC decreases, indicating that the virus is more harmful to the alveoli than the airways.

Preliminary evidence suggests that these lung function abnormalities improve over time (16). Recently, a study described the recovery of lung injury in SARS patients over the past 15 years (17). The results suggested that pulmonary function can be improved to a greater extent when the acute phase of infectious viral pneumonia is effectively managed. In this study, patients were followed up 2 weeks after hospital discharge. The rates of pulmonary dysfunction disorder were significant, and were consistent with the imaging results (Figure 2). However, a 2-week follow-up period is relatively short, and most patients’ lung function and pulmonary fibrosis can be restored (17). These patients should continue to be monitored for any changes in condition and symptoms over a longer period.

Currently, there is no evidence-based medication for treating pulmonary fibrosis caused by viral pneumonia. Nintedanib is a tyrosine kinase inhibitor that is recommended for idiopathic pulmonary fibrosis (IPF). It exerts anti-pulmonary fibrosis activity by inhibiting fibroblast growth factor receptor (FGFR), platelet-derived growth factor receptor (PDGFR), and vascular endothelial growth factor receptor (VEGFR). Studies in mice found
that nintedanib reduces high tidal volume mechanical ventilation-augmented epithelial mesenchymal transition and pulmonary fibrosis after bleomycin-induced acute lung injury (18). However, nintedanib has not been used in pulmonary fibrosis patients undergoing viral pneumonia treatment, warranting further clinical research. Moreover, pulmonary rehabilitation, such as breathing exercises and pulmonary function tests, is necessary for patients with pulmonary fibrosis caused by COVID-19-induced pneumonia. The limitation of the study is the samples were too small. Of course, we need a longer follow-up time to pay attention to the recovery of lung function in patients with COVID-19-induced pneumonia.

**Conclusions**

In summary, we found that the frequency of pulmonary dysfunction in patients with COVID-19-induced pneumonia is relatively high, manifesting as restrictive dysfunction and small airway injury. Our results highlight the need to pay close attention to pulmonary function and strengthen pulmonary function monitoring in these patients, and commence rehabilitation treatment if required.
